A Rickettsiales-like (?) Bacterium Is Responsible For The Tissue Loss Diseases Of Caribbean Acroporid Corals

2014

Esther C. Peters, Ph.D.

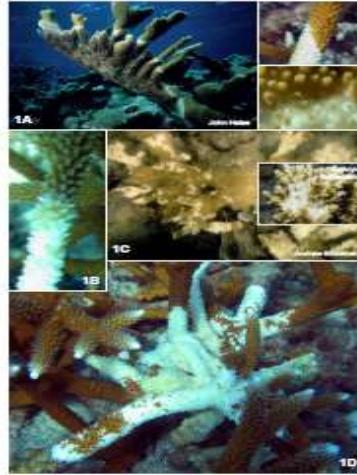

Department of Environmental Science & Policy, George Mason University, Fairfax, Virginia 22030-4444

The Problem

Staghorn (*Acropora cervicornis*), elkhorn (*A. palmata*), and their hybrid (*A. prolifera*) coral populations in the Caribbean Sea and tropical western Atlantic Ocean have declined greatly since the early 1970s. The main cause due to white band disease was first reported (Grafahl et al. 1982; Work et al. 2011). A study of few staghorn were histopathological and microbiological techniques to study the affected corals, despite the importance of doing so to confirm the links between suspected microbial pathogens and tissue damage (e.g., Bythell et al. 2002; Work et al. 2008; Williams et al. 2011).

This report presents progress on a histopathology study based on recent sample collections and archived tissues and histiologies to try to improve our understanding of the tissue loss diseases.

- Four categories of acute to subacute tissue loss (focal, multifocal, or diffuse), not associated with predation by corallivores, have been identified on Caribbean acroporids, based on rate and pattern of tissue loss:
- White-band disease type I (WBD-I) with sloughing or straight tissue loss margin (Fig. 1A), reviewed in Bythell et al. (2008).
- White-band disease type II (WBD-II) with bleaching at tissue loss margin (Fig. 1B), reviewed in Ritchie and Smith (1998).
- White pox or white patch disease (WPD) (Fig. 1C), reviewed in Patterson-Sutherland & Ritchie (2004), and
- Rapid tissue loss (RTL) (Fig. 1D), Williams & Miller (2005).

Identifying the Pathogen

To restore lost acroporid populations, coral nurseries are culturing branch fragments and replanting them on reefs. For this process to be successful, we need to know what causes the tissue loss and whether and how it can be controlled. These studies have reported finding a microorganism that might be the pathogen causing the tissue loss:

- WBD-I: Bacterial aggregates** by histopathology (Peters et al. 1983; not seen in Bythell et al. 2002), identified by Polson (2007) by molecular analysis as Gram-negative *Pseudomonas* spp. Found in apparently healthy samples and not always found in diseased samples.
- WBD-II: Gram-negative *Serratia marcescens*** by microbiology. Koch's postulates satisfied (Sutherland et al. 2011), only found in *A. palmata*.
- WBD-II: Gram-negative *Vibrio caribbeanus*/harveyi** by microbiology (Ritchie & Smith 1998). Koch's postulates almost all satisfied, incomplete (Gili-Aguado et al. 2006).
- WBD-I: Gram-negative *Rickettsiales*-like bacterium** by molecular analysis (90% similarity to uncultured *Rickettsiales* with BLASTN based on cloning and sequencing of bacterial 16S rDNAs) (Casas et al. 2004). Also in apparently healthy staghorn corals and in other coral species, conclusion: not the pathogen of WBD-I.

Should the *Rickettsiales*-like organism (RLO) be dismissed? RLOs are obligate intracellular parasites and known pathogens of many marine organisms. Could they be harmful to corals without causing gross disease signs?

Materials and Methods

Freshly collected and archived preserved specimens of *A. cervicornis*, *A. palmata*, and *A. prolifera* obtained from sites throughout the region. All specimens immersed in a formaldehyde-based fixative, decalcified, paraffin-embedded, and sectioned (Peters et al. 2005). Tissues stained with hematoxylin and eosin (H&E) for examination by light microscopy to detect pathological changes in the tissues. Additional sections stained with a Giemsa method, which is used to detect *Rickettsia* and other Gram-negative bacteria.

Conclusions

Tropical western Atlantic acroporid corals have been infected since the 1970s with an obligate intracellular bacterium that has affinities to the primitive bacterial group *Rickettsiales* (molecular) or *Clostridia* (morphology) (e.g., Fryer & Lanan 1994). The microorganism infects polyp mucocytes, proliferates, and kills them. Additional molecular and ultrastructural studies to determine its identity are in progress.

Koch's Postulates require modifications for determining the pathogenicity of noncultivable microorganisms and other stressors (USEPA 2000). Experimental exposures to *Serratia marcescens* (Patterson et al. 2004) and *Vibrio harveyi* (Gili-Aguado et al. 2006) resulted in tissue loss, but coral condition was not determined by histology. The suspect RLO/CLO is the primary pathogen, continually killing cells. If the coral cannot obtain adequate nutrition to replace these cells and continue vital metabolic functions, it becomes highly susceptible to other agents. Probable secondary pathogens include: other microorganisms; temperature, turbidity, sedimentation stress; or toxicant exposure. Different patterns of tissue loss are probably due to the intensity and duration of infections, and the identity of the secondary stressor(s) that trigger them.

The weakened condition of present populations of acroporids explains the intermittent outbreaks, which may occur during transient exposure to additional stressors but then disappear, and inconsistent transmission of tissue loss. Studies are underway to determine whether larvae are infected, when settled planulae become infected, or if any acroporid genotypes resist infection, and to further explore this challenging enigma.

Results

Fig. 2. Suspected RLO/CLO mucocytes, tentacles.

Carolyn Friedman (University of Washington) identified these structures (Fig. 2) as the suspect RLOs (WBD-affected *A. palmata*) collected by David Kline (University of Miami) in 1983. These 30 histiocytes were prepared since the mid-1970s have been located and many obtained (from International Registry of Coral Pathology, Registry of Tumors in Lower Animals, or collectors). Results of observations to date are in Table 1.

*Not same as in Peters et al. (1983), due to missing histiocytes used to estimate. **= number of histiocytes with RLOs in each sample. AH = apparently healthy, WBD = white band disease, WPO = white patch disease, RTL = rapid tissue loss. *No RLOs in specimens collected in same sample set. Present = suspect RLO. On over 100 of the samples not all of the samples have been examined yet. **= More slides in sets to be examined.

Results, Continued

Tissue sections from acroporid coral samples collected in 1981 from Tague Bay, St. Croix, US Virgin Islands, site of the first WBD-I outbreak were re-examined and the results are presented in Table 2. The histopathological examination of the tissue edge was limited and these microorganisms did not allow to stain well with H&E, possibly also due to variations in fixation and acid decalcification. Giemsa staining is necessary to clearly detect them (Fig. 2). The cells then stain dark reddish-purple.

Table 2. Results of histopathological examinations of most of the samples collected in 1981 from Tague Bay, St. Croix, US Virgin Islands.

Species and Condition	A. cervicornis	A. cervicornis	A. cervicornis	A. cervicornis
